Chiral Spin Mode on the Surface of a Topological Insulator

Using polarization-resolved resonant Raman spectroscopy, we explore collective spin excitations of the chiral surface states in a three dimensional topological insulator, Bi$_2$Se$_3$. We observe a sharp peak at 150 meV in the pseudovector $A_2$ symmetry channel of the Raman spectra. By comparing the data with calculations, we identify this peak as the transverse collective spin mode of surface Dirac fermions. This mode, unlike a Dirac plasmon or a surface plasmon in the charge sector of excitations, is analogous to a spin wave in a partially polarized Fermi liquid, with spin-orbit coupling playing the role of an effective magnetic field.

Magnets and partially spin-polarized Fermi liquids support collective spin excitations (spin waves), in which all electron spins respond coherently to external fields, and the “glue” that locks the phases of precessing spins is provided by the exchange interaction. In nonmagnetic materials where inversion symmetry is broken but time-reversal invariance remains intact, strong spin-orbit coupling (SOC) may play the role of an effective magnetic field, which locks electron spins and momenta into textures. This phenomenon is encountered in three-dimensional (3D) topological insulators (TIs), which harbor topologically protected surface states [1–5]. These states have been a focus of intense studies, both from the fundamental point of view [6–12] and for potential applications in spintronics devices [13–20]. However, the many-body interactions leading to collective effects in TIs remain largely unexplored. An essential aspect of this physics is an interplay between the Coulomb interaction and SOC, which is expected to give rise to a new type of collective spin excitations—chiral spin waves [21–26]. In the long wavelength ($q = 0$) limit, these modes are completely decoupled from the charge channel and thus distinct from spin plasmons [27,28], Dirac plasmons [29,30], and surface plasmons in TIs [30,31].

In this Letter, we employ polarization-resolved resonant Raman spectroscopy, a technique of choice for probing the collective charge [32,33], spin [34–37], and orbital excitations [38], to study collective spin excitations of the chiral surface states in Bi$_2$Se$_3$. To enhance the signal from the surface states, we tune the energy of incoming photons in resonance with a transition between two sets of chiral surface states: near the Fermi energy and about 1.8 eV above it [Fig. 1(a)] [39]. We observe a long-lived excitation at 150 meV in the pseudovector symmetry channel of the Raman spectra, which is most pronounced at low temperatures but persists up to room temperature. By comparing the data with calculations, we identify this excitation as the transverse collective chiral spin mode supported by spin-polarized surface Dirac fermions. Such collective modes—first predicted for nontopological systems [21–26,36], but hitherto unobserved—are “peeled off” from the continuum of particle-hole excitations by the exchange interaction.

Chiral surface states in a 3D TI are described by the Hamiltonian [46]

$$\hat{H}(k) = \frac{k^2}{2m^*} \hat{\sigma}_0 + v_1 \hat{\sigma} \cdot \hat{k},$$

where $m^*$ is the effective mass, $\hat{\sigma} = (\hat{\sigma}_1, \hat{\sigma}_2, \hat{\sigma}_3)$ are the Pauli matrices, $\hat{\sigma}_0$ is the $2 \times 2$ unit matrix, and $\hat{k} = (k_x, -k_y, (v_w/v_1)[k_x^3 + k_y^3])$ with $k_y \equiv k_x \pm ik_y$. The $z$ component of $\hat{k}$ describes hexagonal warping of the surface states away from the Dirac point [46]. The spectrum of Eq. (1) consists of hexagonally warped electronlike and holelike Dirac cones of opposite chirality. A light-induced excitation from the occupied state in the hole cone to an empty state in the electron cone is accompanied by a spin flip of the quasiparticle [Fig. 1(b)]. Such direct transitions form a continuum which starts at the threshold energy $\omega_-$ [Fig. 1(c)] [47,48].

Because of the Pauli exclusion principle, two electrons in a triplet state avoid each other, thus reducing the energy of the Coulomb repulsion. Therefore, the repulsive Coulomb interaction between electrons translates into an attractive exchange interaction between their spins, leading to bound states below the continuum of spin-flip excitation, i.e., chiral spin modes. In general, there are three such modes [red curves in Fig. 1(c)], which correspond to linearly polarized oscillations of the magnetic moment in the...
plane moment, with energies there is a doubly degenerate mode with an in-plane SS2 [Fig.1(a)]. As-grown Bi$_2$Se$_3$, and another pair at about 1.8 eV above SS1, labeled by a pair of topologically protected surface Dirac cones, labeled SS1, through resonant scattering via the intermediate states, SS2. The energy difference between the excited and ground state defines the Raman shift, $\omega_\perp$.

We use 521, 647, 676, and 752 nm lines of a Kr$^+$ laser for excitation, where the spot size is roughly 50 $\times$ 50 $\mu$m$^2$, and the power is about 10 mW. The scattered light is analyzed by a custom triple-grating spectrometer.

In Fig. 2, we show spectra of secondary emission for four scattering geometries employing both linear and circular polarizations, as defined in the Supplemental Material [41]. Of the four excitations, the 521 nm (2.38 eV) one is the farthest from near-resonant transition between SS1 and SS2, while the 676 nm (1.83 eV) one is the closest. The spectra contain contributions from electronic Raman scattering and exciton photoluminescence. The latter is present for all polarizations and can be subtracted from the spectra [41]. The signal below 50 meV is dominated by phonon modes which are discussed elsewhere [54].

The spectrum for the nonresonant 521 nm (2.38 eV) excitation shows no sharp peaks but a broad feature [41]. This is in stark contrast to the spectra of other three excitations, where a sharp peak around 150 meV is observed in the $XY$ and $RR$ geometries. The peak is the strongest for the 676 nm (1.83 eV) excitation, which is in near-resonance with the transition between SS1 and SS2, thus confirming the surface origin of the observed signal. In order to better understand the origin of the 150 meV peak, we subtract the photoluminescence contributions and then utilize the symmetry properties of the Raman tensors to separate the measured spectra into the $E_2$, $A_1$, and $A_2$ symmetry channels of the $C_{6v}$ point group [41]. In Fig. 3, we plot the temperature dependence of the Raman response.

The crystal is composed of quintuple layers weakly bonded by van der Waals force, allowing easy cleavage of optically flat surfaces with the symmorphic $P6_3\overline{m}$ wallpaper group symmetry (2D point group $C_6v$) [50,51]. Bi$_2$Se$_3$ has a relatively simple band structure near the $\Gamma$-point [Fig. 1], with a pair of topologically protected surface Dirac cones, labeled SS1, and another pair at about 1.8 eV above SS1, labeled by SS2 [Fig. 1(a)]. As-grown Bi$_2$Se$_3$ is usually electron doped due to naturally formed Se vacancies [52]. In this study, we use well-characterized samples with low concentration of impurities and crystalline defects [53]. All the bulk phonon modes in this crystal are sharp with no signatures of any impurity modes, and all the surface phonon modes are clearly observed [54]. The Fermi energy ($E_F$) was determined by scanning tunneling spectroscopy to be about 150 meV above the Dirac point of SS1 [Fig. 1(b)] [53].

The polarized Raman spectra were acquired in a quasi-backscattering geometry from the $ab$ surface of Bi$_2$Se$_3$ single crystals grown by the modified Bridgman method [41]. We use 521, 647, 676, and 752 nm lines of a Kr$^+$ laser for excitation, where the spot size is roughly 50 $\times$ 50 $\mu$m$^2$, and the power is about 10 mW. The scattered light is analyzed by a custom triple-grating spectrometer.
It is clearly seen that the 150 meV peak is associated with the $A_2$ symmetry channel. The continuum broadens and becomes invisible above 150 K, but the peak is still well defined even at $T = 300$ K.

The basis functions of the $A_2$ representation of $C_{6v}$ transform as the $z$ component of the angular momentum, which is a pseudovector [55,56]. This suggests that the observed peak in the $A_2$ channel corresponds to a spin mode [marked by $\omega_{s\perp}$ in Fig. 1(c)] with an out-of-plane magnetic moment (also a pseudovector).

To quantify the assignment of the 150 meV peak to the out-of-plane chiral spin mode, we calculate the Raman response of surface chiral states. We are interested in spin-flip resonant Raman processes between states near the Fermi level in SS1 and the states in SS2. Two resonance transitions are possible: an electron from the lower cone of SS1 can be transferred into either the lower or upper cones of SS2 and come back to the upper cone of SS1, producing a particle-hole pair. The diagrams for the corresponding Raman vertex and scattering cross section are shown in Figs. 4(a) and 4(b), correspondingly. Since the shift in the...
photon energy ≈ 150 meV is much smaller than energy difference between the Dirac points $E_g \approx 1.8$ eV, the resonant part of the Raman vertex can be written as

$$\gamma(k) = \frac{(e_S \cdot p_{u_{1,2}})(e_I \cdot p_{u_{1,2}})}{E_{u_{1,2}}(k) - E_{l_{1,2}}(k) - \Omega_L} + \frac{(e_S \cdot p_{l_{1,2}})(e_I \cdot p_{l_{1,2}})}{E_{l_{1,2}}(k) - E_{l_{1,2}}(k) - \Omega_L},$$

(2)

where $l_{1,2}$ and $u_{1,2}$ refer to the lower and upper cones of SS1 (SS2), $p_{ab}$ is the matrix element of a dipole transition between states $a$ and $b$, and $e_{I,S}$ are the polarizations of incident and scattered photons, correspondingly. Furthermore, $E_{u_{1,2}} = \varepsilon^{\pm}_{1,2}(k)$ and $E_{l_{1,2}} = E_0 + \varepsilon^{\pm}_{2,2}(k)$, where $\varepsilon^{\pm}_{1,2}(k) = k^2/2m^* \pm v_1 k$ are the eigenenergies of Eq. (1), and $\varepsilon^{\pm}_{2,2}(k)$ are the eigenenergies of a similar Hamiltonian for SS2. The scattering cross section contains $|\gamma(k)|^2$, integrated over $k \geq k_F$. However, if trigonal warping is neglected, the denominators of the first (second) terms in Eq. (2) become $E_0 + (v_2 \pm v_1)k - \Omega_L$, where $v_{1,2}$ are the velocities of Dirac fermions in SS1 and SS2. A characteristic feature of Bi$_2$Se$_3$ is that the lower cones of SS1 and SS2 are almost perfectly nested: a fit to the ARPES data in Refs. [39,40] gives $v_1 = 2.4$ eV Å and $v_2 = 2.0$ eV Å. Therefore, the second (hole-to-hole) term in $\gamma$ is essentially dispersionless, and the corresponding transition probability is enhanced by a factor of $\approx 1/(E_0 - \Omega_L)^2$, whereas the first (hole-to-electron) term is small [57]. This explains why only one resonance is observed in the experiment.

Since the initial and final states of the Raman vertex form a $2 \times 2$ space, $\tilde{\chi}$ can be expanded over a complete set of Pauli matrices as $\tilde{\chi} = e \tilde{c}_0 + s \cdot \tilde{d}$. In the XY scattering geometry, which contains the $A_2$ symmetry channel of $C_{6v}$ group, $s = e_I \times e_S = e_z$ and, thus, $\tilde{\chi} \propto \tilde{d}$. The Raman response function can then be written as

$$R(\omega, T) \propto \chi^\prime_\alpha(\omega, T)/(E_0 - \Omega_L)^2,$$

(3)

where $\chi^\prime_\alpha$ is the imaginary part of the $\alpha\beta$th component of the spin susceptibility tensor. The many-body interactions are accounted for within the random phase approximation (RPA) with a Hubbard-like interaction ($U$) in the spin channel [25]:

$$\hat{\chi}(\omega, T) = -\Pi(\omega, T) \left( \mathbb{1} + \frac{U}{2} \hat{\Pi}(\omega, T) \right)^{-1},$$

(4)

where $\hat{\Pi}(\omega, T)$ is obtained by analytic continuation of

$$\hat{\Pi}(\omega, T) = T \sum_{i,n} \int_k Tr[\hat{G}_n(\omega + i\omega_n)\hat{G}_k(\omega_n)].$$

Here, $\int_k \equiv \int [d^2k/(2\pi)^2]$, $\hat{G}_k^{-1}(\omega_n) = i\epsilon_n - \hat{H}(k) + E_F + i\text{sgn}(\epsilon_n)\Gamma/2$, $\hat{H}(k)$ is given by Eq. (1), and $\Gamma$ is impurity broadening [58]. $\chi^\prime_\alpha(\omega, T)$ has a continuum of spin-flip excitations and a pole which corresponds to the transverse collective mode. A simple result for the frequency of this mode can be obtained if one neglects hexagonal warping and considers the weak-coupling limit. In this case, $\omega_{\alpha\beta} = 2E_F[1 - 2\exp(-4/\mu)]$, where $\mu = U E_F/2\pi v_F^2 \ll 1$ is the dimensionless coupling constant.

For a more general case, which includes the realistic band structure and finite temperature, the Raman response has to be evaluated numerically. The results of this calculation are shown in Fig. 3(d). With the band structure parameters obtained from ARPES measurements [40], the only two fitting parameters are the exchange coupling constant, fixed at $u \approx 0.6$ to reproduce the mode frequency at 15 K, and the impurity scattering rate chosen as $\Gamma = 8$ meV. Comparison of the measured and computed spectra [Figs. 3(c) and 3(d), correspondingly] shows that the model describes well not only the overall shape of the signal but also its evolution with temperature [41]. In particular, the theory reproduces the observed decrease in the peak position with increasing temperature, which can be ascribed to thermal smearing of the continuum boundary. For the well-characterized samples studied here, the threshold of the spin-flip continuum is expected at $\omega_{\alpha} \approx 260$ meV [41]. However, the onset of this continuum is difficult to observe because its spectral weight is transferred into the collective mode. In the inset of Fig. 3(d), we show an enlargement of the computed crossover region between the collective mode and the continuum. A quantitative agreement between theory and experiment gives us confidence that the observed 150 meV sharp peak in the $A_2$ symmetry channel is indeed a transverse chiral spin mode.

In conclusion, our results provide strong evidence for a new collective mode—the transverse chiral spin wave—in a time-reversal invariant system, a 3D TI. Strong spin-orbit coupling plays the role of a very high effective magnetic field, which protects the long-lived spin excitation. Such a robust collective spin mode may have potential applications in spintronics [59,60], magnonics [61–63], optoelectronics [64], and quantum computing [65–67]. Moreover, the present results demonstrate an efficient way of probing...
the dynamical response of Dirac fermions and their collective modes through optical measurement. The methods we use here pave a new route for discriminating bulk excitations from the surface modes and for exploring collective properties of chiral fermions.
